## Abstract

- 1  
2       1. The effect of explanatory environmental variables on a species'  
3       distribution is often assessed using a count regression model.  
4       Poisson generalised linear models or negative binomial models  
5       are common, but the traditional approach of modelling the mean  
6       after log or square-root transformation remains popular and in  
7       some cases is even advocated.
- 8       2. We propose a novel class of linear models for count data. Sim-  
9       ilar to the traditional approach, the new models apply a trans-  
10       formation to count responses; however, this transformation is  
11       estimated from the data and not defined a priori. In contrast  
12       to simple least-squares fitting and in line with Poisson or nega-  
13       tive binomial models, the exact discrete likelihood is optimised  
14       for parameter estimation and inference. Interpretation of linear  
15       predictors is possible at various scales depending on the model  
16       formulation.
- 17       3. Count transformation models provide a new approach to regress-  
18       ing count data in a distribution-free yet fully parametric fashion,  
19       obviating the need to a priori commit to a specific parametric  
20       family of distributions or to a specific transformation. The model  
21       class is a generalisation of discrete Weibull models for counts and  
22       is thus able to handle over- and underdispersion. We demon-

23           strate empirically that the models are more flexible than Poisson  
24           or negative binomial models but still maintain interpretability of  
25           multiplicative effects. A re-analysis of deer-vehicle collisions and  
26           the results of artificial simulation experiments provide evidence  
27           of the practical applicability of the model class.

28           4. In ecology studies, uncertainties regarding whether and how to  
29           transform count data can be resolved in the framework of count  
30           transformation models, which were designed to simultaneously  
31           estimate an appropriate transformation and the linear effects  
32           of environmental variables by maximising the exact count log-  
33           likelihood. The application of data-driven transformations al-  
34           lows over- and underdispersion to be addressed in a model-based  
35           approach. Competing models in this class can be compared  
36           to Poisson or negative binomial models using the in- or out-  
37           of-sample log-likelihood. Extensions to non-linear additive or  
38           interaction effects, correlated observations, hurdle-type models  
39           and other, more complex situations are possible. A free software  
40           implementation is available in the **cotram** add-on package to  
41           the R system for statistical computing.

# 44 1 Introduction

45 Information represented by counts is ubiquitous in ecology. Perhaps the  
46 most obvious instance of ecological count data is animal abundances, which  
47 are determined either directly, for example by birdwatchers, or indirectly, by  
48 the counting of surrogates, for example the number of deer-vehicle collisions  
49 as a proxy for roe deer abundance. This information is later converted into  
50 models of animal densities or species distributions using statistical models  
51 for count data. Distributions of count data are, of course, discrete and right-  
52 skewed, such that tailored statistical models are required for data analysis.  
53 Here we focus on models explaining the impact of explanatory environmental  
54 variables  $\mathbf{x}$  on the distribution of a count response  $Y \in \{0, 1, 2, \dots\}$ . In the  
55 commonly used Poisson generalised linear model  $Y | \mathbf{x} \sim \text{Po}(\exp(\alpha + \mathbf{x}^\top \boldsymbol{\beta}))$   
56 with log-link, intercept  $\alpha$  and linear predictor  $\mathbf{x}^\top \boldsymbol{\beta}$ , both the mean  $\mathbb{E}(Y | \mathbf{x})$   
57 and the variance  $\mathbb{V}(Y | \mathbf{x})$  of the count response are given by  $\exp(\alpha + \mathbf{x}^\top \boldsymbol{\beta})$ .  
58 Overdispersion, *i.e.* the situation  $\mathbb{E}(Y | \mathbf{x}) < \mathbb{V}(Y | \mathbf{x})$ , is allowed in the  
59 more complex negative binomial model  $Y | \mathbf{x} \sim \text{NB}(\exp(\alpha + \mathbf{x}^\top \boldsymbol{\beta}), \nu)$  with  
60 mean  $\mathbb{E}(Y | \mathbf{x}) = \exp(\alpha + \mathbf{x}^\top \boldsymbol{\beta})$  and potentially larger variance  $\mathbb{V}(Y | \mathbf{x}) =$   
61  $\mathbb{E}(Y | \mathbf{x}) + \mathbb{E}(Y | \mathbf{x})^2 / \nu$ . For independent observations, the model parameters  
62 are obtained by maximising the discrete log-likelihood function, in which an  
63 observation  $(y, \mathbf{x})$  contributes the log-density  $\log(\mathbb{P}(Y = y | \mathbf{x}))$  of either the

64 Poisson or the negative binomial distribution.

65 Before the emergence of these models tailored to the analysis of count data  
66 (generalised linear models were introduced by [Nelder & Wedderburn 1972](#)),  
67 researchers were restricted to analysing transformations of  $Y$  by normal linear  
68 regression models. Prominent textbooks at the time ([Snedecor & Cochran](#)  
69 [1967](#); [Sokal & Rohlf 1967](#)) suggested log transformations  $\log(y+1)$  or square-  
70 root transformations  $\sqrt{y+0.5}$  of observed counts  $y$ . The application of least-  
71 squares estimators to the log-transformed counts then leads to the mean  
72  $\mathbb{E}(\log(y+1) \mid \mathbf{x}) = \alpha + \mathbf{x}^\top \boldsymbol{\beta}$ . Implicitly, it is assumed that the variance  
73 after transformation  $\mathbb{V}(\log(y+1) \mid \mathbf{x}) = \sigma^2$  is constant and that errors  
74 are normally distributed. Although it is clear that the normal assumption  
75  $\log(Y+1) \mid \mathbf{x} \sim \text{N}(\alpha + \mathbf{x}^\top \boldsymbol{\beta}, \sigma^2)$  is incorrect (the count data are still discrete  
76 after transformation) and, consequently, that the wrong likelihood is max-  
77 imised by applying least-squares to  $\log(y+1)$  for parameter estimation and  
78 inference, this approach is still broadly used both in practice and in theory  
79 (*e.g.* [Ives 2015](#); [Dean, Voss & Draguljić 2017](#); [Gotelli & Ellison 2013](#); [De Fe-](#)  
80 [lipse, Sáez-Gómez & Camacho 2019](#); [Mooney, Phillips, Tillberg, Sandrow,](#)  
81 [Nelson & Mooney 2016](#)). Moreover, other deficits of this approach have been  
82 discussed in numerous papers (*e.g.* [O’Hara & Kotze 2010](#); [Warton, Lyons,](#)  
83 [Stoklosa & Ives 2016](#); [St-Pierre, Shikon & Schneider 2018](#); [Warton 2018](#)).

84 As a compromise between the two extremes of using rather strict count dis-

85 tribution models (such as the Poisson or negative binomial) and the analysis  
86 of transformed counts by normal linear regression models, we suggest a novel  
87 class of transformation models for count data that combines the strengths of  
88 both approaches. Briefly stated, in the newly proposed method appropriate  
89 transformations of counts  $Y$  are estimated simultaneously with regression  
90 coefficients  $\boldsymbol{\beta}$  from the data by maximising the correct discrete form of the  
91 likelihood in models that ensure the interpretability of a linear predictor  
92  $\boldsymbol{x}^\top \boldsymbol{\beta}$  on an appropriate scale. We describe the theoretical foundations of  
93 these novel count regression models in Section 2. Practical aspects of the  
94 methodology are demonstrated in Section 3 in a re-analysis of roe deer ac-  
95 tivity patterns based on deer-vehicle collision data, followed by an artificial  
96 simulation experiment contrasting the performance of Poisson, negative bi-  
97 nomial and count transformation models under certain conditions.

## 98 **2 Methods**

The core idea of our count transformation model for describing the impact of explanatory environmental variables  $\boldsymbol{x}$  on counts  $Y \in \{0, 1, 2, \dots\}$  is the simultaneous estimation of a fully parameterised smooth transformation  $h_Y(Y)$  of the discrete response and the regression coefficients in a linear predictor  $\boldsymbol{x}^\top \boldsymbol{\beta}$ . The aim of the approach is to model the discrete conditional distribu-

tion function  $F_{Y|\mathbf{X}=\mathbf{x}}$  directly. Specifically, for any positive real number  $y$  we evaluate the conditional distribution function as

$$F_{Y|\mathbf{X}=\mathbf{x}}(y | \mathbf{x}) = \mathbb{P}(Y \leq y | \mathbf{x}) = F_Z(h_Y(\lfloor y \rfloor) - \mathbf{x}^\top \boldsymbol{\beta}), \quad y \in \mathbb{R}^+ \quad (1)$$

with  $h_Y : \mathbb{R}^+ \rightarrow \mathbb{R}$  being an unknown, monotonically increasing continuous transformation function applied to the greatest integer  $\lfloor y \rfloor$  less than or equal to  $y$ . Specific models in this class arise from the different a priori choices of the inverse link function  $F_Z : \mathbb{R} \rightarrow [0, 1]$  and the parameterisation of  $h_Y$ . [Hothorn, Möst & Bühlmann \(2018\)](#) suggested the parameterisation of  $h_Y$  in terms of basis functions  $\mathbf{a} : \mathbb{R} \rightarrow \mathbb{R}^P$  and the corresponding parameters  $\boldsymbol{\vartheta}$  as

$$h_Y(y) = \mathbf{a}(y)^\top \boldsymbol{\vartheta}.$$

99 The only modification required for count data is to consider this transfor-  
 100 mation function as a step function with jumps at integers  $0, 1, 2, \dots$  only.  
 101 This is achieved in model (1) by the floor function  $\lfloor y \rfloor$ . The very same  
 102 approach was suggested by [Padellini & Rue \(2019\)](#) but to model quantile  
 103 functions  $F_{Y|\mathbf{X}=\mathbf{x}}^{-1}$  of count data instead of the distribution functions we con-  
 104 sider here. Figure 1 shows a distribution function  $F_Y(y) = F_Z(h_Y(\lfloor y \rfloor))$   
 105 and the corresponding transformation function  $h_Y$ , both as discrete step-  
 106 functions (flooring the argument first) and continuously (without doing so).  
 107 The two versions are identical for integer-valued arguments. Thus, the trans-  
 108 formation function  $h_Y$ , and consequently the transformation model (1), are

109 parameterised continuously but evaluated and interpreted discretely. A com-  
 110 putationally attractive, low-dimensional representation of a smooth function  
 111 in terms of a few basis functions  $\mathbf{a}$  and corresponding parameters is therefore  
 112 the core ingredient of our novel model class.

113 [Figure 1 about here.]

114 On a more technical level, the basis  $\mathbf{a}$  is specified in terms of  $\mathbf{a}_{\text{Bs},P-1}$ , with  
 115  $P$ -dimensional basis functions of a Bernstein polynomial (Farouki 2012) of  
 116 order  $P - 1$ . Specifically, the basis  $\mathbf{a}(y)$  can be chosen as:  $\mathbf{a}_{\text{Bs},P-1}(y)$  or  
 117  $\mathbf{a}_{\text{Bs},P-1}(y + 1)$ , or as a Bernstein polynomial on the log-scale:  $\mathbf{a}_{\text{Bs},P-1}(\log(y))$   
 118 or  $\mathbf{a}_{\text{Bs},P-1}(\log(y + 1))$ . The choice of  $\mathbf{a}(y) = \mathbf{a}_{\text{Bs},P-1}(\log(y + 1))$  is particularly  
 119 well suited for modelling relatively small counts. For  $P = 1$ , the defined basis  
 120 is equivalent to a linear function of either  $y$ ,  $\log(y)$  or  $\log(y + 1)$ . Monotonicity  
 121 of the transformation function  $h_Y$  can be obtained under the constraint  $\vartheta_1 \leq$   
 122  $\vartheta_2 \leq \dots \leq \vartheta_P$  of the parameters  $\boldsymbol{\vartheta} = (\vartheta_1, \dots, \vartheta_P)^\top \in \mathbb{R}^P$  (Hothorn et al.  
 123 2018).

124 The monotonically increasing continuous inverse link function  $F_Z : \mathbb{R} \rightarrow$   
 125  $[0, 1]$  governs the interpretation of the linear predictor  $\mathbf{x}^\top \boldsymbol{\beta}$ . The conditional  
 126 distribution function  $F_{Y|\mathbf{X}=\mathbf{x}}(y | \mathbf{x})$  for different choices of the link function  
 127  $F_Z^{-1}$  and any configuration  $\mathbf{x}$  are given in Table 1, with  $F_Y(y) = F_Z(h_Y(\lfloor y \rfloor))$   
 128 denoting the distribution of the baseline configuration  $\mathbf{x}^\top \boldsymbol{\beta} = 0$ . Note that,

129 with a sufficiently flexible parameterisation of the transformation function  
130  $h(y) = \mathbf{a}(y)^\top \boldsymbol{\vartheta}$ , every distribution can be written in this way such that the  
131 model is distribution-free (Hothorn et al. 2018).  
132 The parameters  $\boldsymbol{\beta}$  describe a deviation from this baseline distribution in  
133 terms of the linear predictor  $\mathbf{x}^\top \boldsymbol{\beta}$ . For a probit link, the linear predictor  
134 is the conditional mean of the transformed counts  $h_Y(Y)$ . This interpreta-  
135 tion, except for the fact that the intercept  $\alpha$  is understood as being part of  
136 the transformation function  $h_Y$ , is the same as in the traditional approach  
137 of first transforming the counts and only then estimating the mean using  
138 least-squares. However, the transformation  $h_Y$  is not heuristically chosen  
139 or defined a priori but estimated from data through parameters  $\boldsymbol{\vartheta}$ , as ex-  
140 plained below. For a logit link,  $\exp(-\mathbf{x}^\top \boldsymbol{\beta})$  is the odds ratio comparing  
141 the conditional odds  $F_{Y|\mathbf{X}=\mathbf{x}}/1-F_{Y|\mathbf{X}=\mathbf{x}}$  with the baseline odds  $F_Y/1-F_Y$ . The  
142 complementary log-log (cloglog) link leads to a discrete version of the Cox  
143 proportional hazards model, such that  $\exp(-\mathbf{x}^\top \boldsymbol{\beta})$  is the hazard ratio com-  
144 paring the conditional cumulative hazard function  $\log(1 - F_{Y|\mathbf{X}=\mathbf{x}})$  with the  
145 baseline cumulative hazard function  $\log(1 - F_Y)$ . The log-log link leads to the  
146 reverse time hazard ratio with multiplicative changes in  $\log(F_Y)$ . All models  
147 in Table 1 are parameterised to relate positive values of  $\mathbf{x}^\top \boldsymbol{\beta}$  to larger means  
148 independent of the specified link  $F_Z^{-1}$ .

[Table 1 about here.]

There is a very close connection between generalised linear models for binary data and our transformation model (1). For any dichotomisation of the counts  $\mathbb{1}(Y \leq y)$ , the generalised linear model

$$F_Z^{-1}(\mathbb{E}(\mathbb{1}(Y \leq y) \mid \mathbf{x})) = F_Z^{-1}(\mathbb{P}(\mathbb{1}(Y \leq y) \mid \mathbf{x})) = \alpha(y) - \mathbf{x}^\top \boldsymbol{\beta}$$

150 features an intercept  $\alpha(y)$  that depends on the cut-off  $y$  while the regression  
 151 coefficients  $\boldsymbol{\beta}$  are treated as constant across all possible cut-off values  $y \in$   
 152  $\{0, 1, 2, \dots\}$ . Our transformation model (1) arises from the choice  $\alpha(y) =$   
 153  $h_Y(y)$ , and the transformation function can thus be interpreted as a response-  
 154 varying intercept in binomial generalised linear models with different link  
 155 functions  $F_Z^{-1}$ .

In Section 3.1 of our empirical evaluation we consider a linear count transformation model for discrete hazards by specifying the cloglog link. The discrete Cox count transformation model

$$\begin{aligned} F_{Y|\mathbf{X}=\mathbf{x}}(y \mid \mathbf{x}) &= \mathbb{P}(Y \leq y \mid \mathbf{x}) & (2) \\ &= 1 - \exp\left(-\exp\left(\mathbf{a}_{\text{Bs}, P-1}(\log(\lfloor y + 1 \rfloor))^\top \boldsymbol{\vartheta} - \mathbf{x}^\top \boldsymbol{\beta}\right)\right) \end{aligned}$$

with  $P$  Bernstein basis functions  $\mathbf{a}_{\text{Bs}, P-1}$  relates positive linear predictors to smaller hazards and thus larger means. The discrete hazard function  $\mathbb{P}(Y = y \mid Y \geq y, \mathbf{x})$  is the probability that  $y$  counts will be observed given

that at least  $y$  counts were already observed. The model is equivalent to

$$\mathbb{P}(Y = y \mid Y \geq y, \mathbf{x}) = \exp(-\mathbf{x}^\top \boldsymbol{\beta}) \mathbb{P}(Y = y \mid Y \geq y)$$

156 and thus the hazard ratio  $\exp(-\mathbf{x}^\top \boldsymbol{\beta})$  gives the multiplicative change in  
157 discrete hazards.

158 The Cox proportional hazards model with a simplified transformation func-  
159 tion  $h_Y(y) = \vartheta_1 + \vartheta_2 \log(y + 1)$  specifies a discrete form of a Weibull model  
160 (introduced by Nakagawa & Osaki 1975) that Peluso, Vinciotti & Yu (2019)  
161 recently discussed as an extension to other count regression models and that  
162 serves as a more flexible approach for both over- and underdispersed data.  
163 The discrete Weibull model is a special form of our Cox count transformation  
164 model (2), as the former features a linear basis function  $\mathbf{a}$  with  $P = 2$  param-  
165 eters defined by a Bernstein polynomial of order one. Thus, model (2) can be  
166 understood as a generalisation moving away from the low-parametric discrete  
167 Weibull distribution while maintaining both the interpretability of the effects  
168 as log-hazard ratios and the ability to handle over- and underdispersion.

Simultaneous likelihood-based inference for  $\boldsymbol{\vartheta}$  and  $\boldsymbol{\beta}$  for fully parameterised  
transformation models was developed by Hothorn et al. (2018); here we refer  
only to the most important aspects. The exact log-likelihood of the model  
for independent observations  $(y_i, \mathbf{x}_i), i = 1, \dots, N$  is given by the sum of the

$N$  contributions

$$\ell_i(\boldsymbol{\vartheta}, \boldsymbol{\beta}) = \log(\mathbb{P}(Y = y_i \mid \mathbf{x}_i)) = \begin{cases} \log [F_Z \{ \mathbf{a}(0)^\top \boldsymbol{\vartheta} - \mathbf{x}_i^\top \boldsymbol{\beta} \}] & y_i = 0 \\ \log [F_Z \{ \mathbf{a}(y_i)^\top \boldsymbol{\vartheta} - \mathbf{x}_i^\top \boldsymbol{\beta} \} - F_Z \{ \mathbf{a}(y_i - 1)^\top \boldsymbol{\vartheta} - \mathbf{x}_i^\top \boldsymbol{\beta} \}] & y_i > 0. \end{cases}$$

The corresponding log-likelihood is then maximised simultaneously with respect to both  $\boldsymbol{\vartheta}$  and  $\boldsymbol{\beta}$  under suitable constraints:

$$(\hat{\boldsymbol{\vartheta}}_N, \hat{\boldsymbol{\beta}}_N) = \arg \max_{\boldsymbol{\vartheta}, \boldsymbol{\beta}} \sum_{i=1}^N \ell_i(\boldsymbol{\vartheta}, \boldsymbol{\beta}) \quad \text{subject to } \vartheta_p \leq \vartheta_{p+1}, p \in 1, \dots, P-1.$$

169 Score functions and Hessians are available from [Hothorn et al. \(2018\)](#).

## 170 **3 Results**

171 In our empirical evaluation of the proposed count transformation models,  
 172 we demonstrate practical aspects of the model class in Section 3.1, by re-  
 173 analysing data on deer-vehicle collisions, and examine their properties in the  
 174 context of conventional count regression models, assuming either a condi-  
 175 tional Poisson or a negative binomial distribution. In Section 3.2, we use  
 176 simulated count data to evaluate the robustness of count transformation  
 177 models under model misspecification.

### 178 **3.1 Analysis of deer-vehicle collision data**

179 In the following, we re-analyse a time series of 341'655 deer-vehicle colli-  
180 sions involving roe deer (*Capreolus capreolus*) that were documented between  
181 2002-01-01 and 2011-12-31 in Bavaria, Germany. The roe deer-vehicle col-  
182 lisions, recorded in 30-minute time intervals in the whole of Bavaria, were  
183 originally analysed by [Hothorn, Müller, Held, Möst & Mysterud \(2015\)](#) with  
184 the aim of describing temporal patterns in roe deer activity. The raw data  
185 and a detailed description of their analysis are available in the original study.  
186 In our re-analysis, we explore the estimates and properties of count regression  
187 models explaining how the risk of roe deer-vehicle collisions varies over days  
188 (diurnal effects) as well as across weeks, seasons and the whole year. We  
189 applied a Poisson generalised linear model with a log link, a negative binomial  
190 model with a log link and a discrete Cox count transformation model (2) with  
191  $P = 7$  parameters  $\boldsymbol{\vartheta}$  of a Bernstein polynomial. The latter two models allow  
192 for possible overdispersion. The temporal changes in the risk of roe deer-  
193 vehicle collisions were modelled as a function of the following explanatory  
194 variables: annual, weekly and diurnal effects, an interaction of the weekly  
195 and diurnal effects, and seasonal effects, encoded as interactions of diurnal  
196 effects with a smooth seasonal component  $s(d)$  (based on [Held & Paul 2012](#)).  
197 The three models were fitted to the data of the first eight years (2002 to

198 2009) and evaluated based on the data from the remaining two years, 2010  
199 and 2011.

200 For each model we computed the estimated multiplicative seasonal changes  
201 in risk depending on the time of day relative to baseline on January 1st,  
202 including 95% simultaneous confidence bands. We interpreted “risk” as a  
203 multiplicative change to baseline with respect to either the conditional mean  
204 (“expectation ratio”; Poisson and negative binomial models) or the condi-  
205 tional discrete hazard function (“hazard ratio”) for the Cox count transfor-  
206 mation model (2).

207 [Figure 2 about here.]

208 The results in Figure 2 show a rather strong agreement between the three  
209 models with respect to the estimated risk (expectation ratio or hazard ratio).  
210 However, the uncertainty, assessed by the 95% confidence bands, was under-  
211 estimated in the Poisson model. The negative binomial and the Cox count  
212 transformation model (2) agree on the effects and the associated variability,  
213 with the possible exception of the risk at daylight (Day, am).

214 To assess the performance of the three count regression models, we computed  
215 the out-of-sample log-likelihoods of each model based on the data of the  
216 validation sample (year 2010 and 2011). The out-of-sample log-likelihood of  
217 the Cox count transformation model (2) with a value of  $-58'164.47$  was the

218 largest across the three count regression models. The Poisson model, with an  
219 out-of-sample log-likelihood of  $-67'192.75$ , was the most inconsistent with  
220 the data. Allowing for possible overdispersion by the negative binomial model  
221 increased the out-of-sample log-likelihood to  $-58'234.72$ , which was closer to  
222 but did not match the out-of-sample log-likelihood of model (2).

223 We further compared the three different models in terms of their conditional  
224 distribution functions for four selected time intervals of the year 2009. The  
225 discrete conditional distribution functions of the models, evaluated for all  
226 integers between 0 and 38, are given in Figure 3. The conditional medians  
227 obtained from all three models are rather close, but the variability assessed  
228 by the Poisson model is much smaller than that associated with the negative  
229 binomial and count transformation models, thus indicating overdispersion.

230 [Figure 3 about here.]

## 231 **3.2 Artificial count-data-generating processes**

232 We investigated the performance of the different regression models in a  
233 simulation experiment based on count data from various underlying data-  
234 generating processes (DGPs). Count responses  $Y$  were generated condition-  
235 ally on a numeric predictor variable  $x \in [0, 1]$  following a Poisson or negative-  
236 binomial distribution or one of the discrete distributions underlying the four

237 count transformation models corresponding to the four link functions from  
238 Table 1. For the Poisson model, the mean and variance were assumed to be  
239  $\mathbb{E}(Y | \mathbf{x}) = \mathbb{V}(Y | \mathbf{x}) = \exp(1.2 + 0.8\mathbf{x})$ . The negative binomial data were  
240 chosen to be moderately overdispersed, with  $\mathbb{E}(Y | \mathbf{x}) = \exp(1.2 + 0.8\mathbf{x})$  and  
241  $\mathbb{V}(Y | \mathbf{x}) = \mathbb{E}(Y | \mathbf{x}) + \mathbb{E}(Y | \mathbf{x})^2/3$ . The four data-generating processes  
242 arising from the count transformation models were specified by the different  
243 link functions in Table 1, a Bernstein polynomial  $\mathbf{a}_{\text{Bs},6}(\log(y + 1))$  and a  
244 regression coefficient  $\beta_1 = 0.8$ .

245 We repeated the simulation experiment for each count-data-generating pro-  
246 cess 100 times, with learning and validation sample sizes of  $N = 250$  and  
247  $\tilde{N} = 750$  respectively. The centred out-of-sample log-likelihoods, contrasting  
248 the model fit, were computed by the differences between the out-of-sample  
249 log-likelihoods of the models and the out-of-sample log-likelihoods of the true  
250 generating processes.

251 [Figure 4 about here.]

252 The results as given in Figure 4 follow a clear pattern. When misspecified,  
253 the model fit of the Poisson model is inferior to that of all other models. As  
254 expected, the negative-binomial model well fits both the data arising from  
255 the Poisson distribution (limiting case of the negative-binomial distribution  
256 with  $\nu \rightarrow \infty$ ) and the moderately overdispersed data. However, it lacks ro-

257 bustness for more complex data-generating processes, such as the underlying  
258 mechanisms specified by a count transformation model. The fit of the count  
259 transformation models is satisfactory across all DGPs, albeit with some dif-  
260 ferences within the model class.

## 261 **4 Discussion**

262 Motivated by the challenges posed by the statistical analysis of ecological  
263 count data, we present a novel class of count transformation models that  
264 provide a unified approach tailored to the analysis of count responses. The  
265 model class, as outlined in Section 2, offers a diverse set of count models and  
266 can be specified, estimated and evaluated in a simple but flexible maximum  
267 likelihood framework. The direct modelling of the conditional discrete distri-  
268 bution, while preserving the interpretability of the linear predictor  $\mathbf{x}^\top \boldsymbol{\beta}$ , is  
269 a key feature of our count transformation model. Furthermore, it eliminates  
270 the need to impose restrictive distributional assumptions, to choose transfor-  
271 mations in a data-free manner or to rely on rough approximations of the exact  
272 likelihood. The models are flexible enough to handle different dispersion lev-  
273 els adaptively, without being restricted to either over- or underdispersion.  
274 Our results from the re-analysis of deer-vehicle collision data, presented in  
275 Section 3.1, demonstrate the favourable properties of count transformations

276 in practice. They are especially compelling for the analysis of count responses  
277 arising from more complex data-generating processes, for which the Poisson  
278 and even the more flexible negative binomial distribution are of limited use  
279 (as illustrated in Section 3.2). Moreover, conditional quantiles can be easily  
280 extracted from the fitted model by numerical inversion of the smooth con-  
281 ditional distribution function  $F_Z(h_Y(y) - \mathbf{x}^\top \boldsymbol{\beta})$ . An additional advantage  
282 of count transformation models is that the model class allows researchers to  
283 flexibly choose the scale of the interpretation of the linear predictor  $\mathbf{x}^\top \boldsymbol{\beta}$  by  
284 specifying a link function  $F_Z^{-1}$  from Table 1.

285 The model class can be easily tailored to the experimental design using strata-  
286 specific transformation functions  $h_Y(\lfloor y \rfloor \mid \text{strata})$  or response-varying effects  
287  $\boldsymbol{\beta}(\lfloor y \rfloor)$ . Correlated observations arising from clustered data require the in-  
288 clusion of random effects with subsequent application of a Laplace approxi-  
289 mation to the likelihood. Accounting for varying observation times or batch  
290 sizes is straightforward by the inclusion of an offset in the model specifica-  
291 tion. Random censoring is easy to incorporate in the likelihood (Hothorn  
292 et al. 2018), which can then appropriately handle uncertain recordings (for  
293 example, the observation “more than three roe-deer vehicle collisions in half  
294 an hour” corresponds to right-censoring at three). The same applies to trun-  
295 cation. By contrast, hurdle-like transformation models require modifications  
296 of the basis functions as well as interactions between the response and ex-

297 planatory variables (see Section 4.5 in [Hothorn et al. 2018](#)).

298 Extensions to the proposed simple shift count transformation model can be  
299 made by boosting algorithms ([Hothorn 2019b](#)) that allow the estimation of  
300 conditional transformation models ([Hothorn, Kneib & Bühlmann 2014](#)) fea-  
301 turing complex, non-linear, additive or completely unstructured tree-based  
302 conditional parameter functions  $\boldsymbol{\vartheta}(\boldsymbol{x})$ . Similarly, count transformation mod-  
303 els can be partitioned by transformation trees ([Hothorn & Zeileis 2017](#)),  
304 which in turn lead to transformation forests, as a statistical learning ap-  
305 proach for computing predictive distributions.

306 The greatest challenge in applying count transformation models is their in-  
307 terpretability. The effects of the explanatory environmental variables are not  
308 directly interpretable as multiplicative changes in the conditional mean of the  
309 count response, as is the case in Poisson or negative binomial models with a  
310 log link. For the logit, cloglog and log-log link functions, the effects are still  
311 multiplicative, but at the scales of the discrete odds ratio, hazard ratio or  
312 reverse time hazard ratio, which might be difficult to communicate to prac-  
313 titioners. If the probit link is used, the effects are interpretable as changes in  
314 the conditional mean of the transformed counts. This interpretation is the  
315 same as that obtained from running a normal linear regression model on, for  
316 example, log-transformed counts, with the important difference that (i) the  
317 transformation was estimated from data by optimising (ii) the exact discrete

318 likelihood. Nonetheless, it is possible to plot the estimated transformation  
319 function  $\mathbf{a}(y)^\top \hat{\boldsymbol{\theta}}$  against  $\log(y + 1)$  ex post to assess the appropriateness of  
320 applying a log-transformation.

## 321 **Computational details**

322 All computations were performed using R version 3.6.1 (R Core Team 2019).  
323 A reference implementation of transformation models is available in the **mlt**  
324 R add-on package (Hothorn 2019a; 2018). A simple user interface to lin-  
325 ear count transformation models is available in the **cotram** add-on package  
326 (Siegfried & Hothorn 2019).

327 The following example demonstrates the functionality of the **cotram** pack-  
328 age in terms of a count transformation model with a cloglog link explaining  
329 how the number of tree pipits (*Anthus trivialis*) varies across different per-  
330 centages of canopy overstorey cover (coverstorey).

logit	$\frac{F_{Y \mathbf{X}=\mathbf{x}}(y \mathbf{x})}{1-F_{Y \mathbf{X}=\mathbf{x}}(y \mathbf{x})} = \exp(-\mathbf{x}^\top \boldsymbol{\beta}) \frac{F_Y(y)}{1-F_Y(y)}$
cloglog	$1 - F_{Y \mathbf{X}=\mathbf{x}}(y   \mathbf{x}) = (1 - F_Y(y))^{\exp(-\mathbf{x}^\top \boldsymbol{\beta})}$
loglog	$F_{Y \mathbf{X}=\mathbf{x}}(y   \mathbf{x}) = F_Y(y)^{\exp(\mathbf{x}^\top \boldsymbol{\beta})}$

Table 1: Transformation Model. Interpretation of linear predictors  $\mathbf{x}^\top \boldsymbol{\beta}$  under different link functions  $F_Z^{-1}$ .

412 **List of Figures**

413 1 Transformation model. Illustration of a cumulative distribu-  
414 tion function ( $F_Y(y) = F_Z(h_Y(\lfloor y \rfloor))$ , left) and of a transfor-  
415 mation function ( $h_Y$ , right) of a count response (red) and a  
416 corresponding continuous variable (blue). Note that the two  
417 functions coincide for counts  $0, 1, 2, \dots$  . . . . . 30

418 2 Deer-vehicle collisions. Multiplicative seasonal changes (ref-  
419 erence: January 1 at the corresponding time of day) with si-  
420 multaneous 95% confidence bands for the expected number of  
421 deer-vehicle collisions (modelled by the Poisson model with a  
422 log link (A) and the negative binomial model with a log link  
423 (B)), and for the discrete hazard ratios modelled by the Cox  
424 count transformation model (2) (C). . . . . 31

425 3 Deer-vehicle collisions. Distributions of the deer-vehicle colli-  
426 sion counts conditional on the explanatory environmental pa-  
427 rameters of four different time intervals of the year 2009 eval-  
428 uated for the discrete Cox count transformation model (2)  
429 (red), the Poisson model (blue) and the negative binomial  
430 model (green). The actually observed deer-vehicle collision  
431 counts are shown as a vertical black line. . . . . 32

432 4 Artificial count-data-generating processes (DGPs). The per-  
433 formance of the count regression models (Poisson, negative bi-  
434 nomial and count transformation models outlined in Table 1)  
435 assessed by the centered out-of-sample log-likelihood of the  
436 corresponding model. Larger values of the out-of-sample log-  
437 likelihood indicate a better performance of the corresponding  
438 count regression model. . . . . 33

439 5 Tree pipit illustration. Number of tree pipits counted at 86 dif-  
440 ferent plots with varying coverstorey. The sizes of the circles  
441 are proportional to the square-root of the sample size. Ob-  
442 servations are overlaid with the smoothed conditional distri-  
443 bution functions. For a coverstorey of 20%, for example, the  
444 probability of not observing any tree pipit is slightly larger  
445 than 0.65, the probability of observing at most one tree pipit  
446 is somewhat larger than 0.70. For a coverstorey of 60%, the  
447 probability of observing at least one tree pipit is less than 0.1. 34

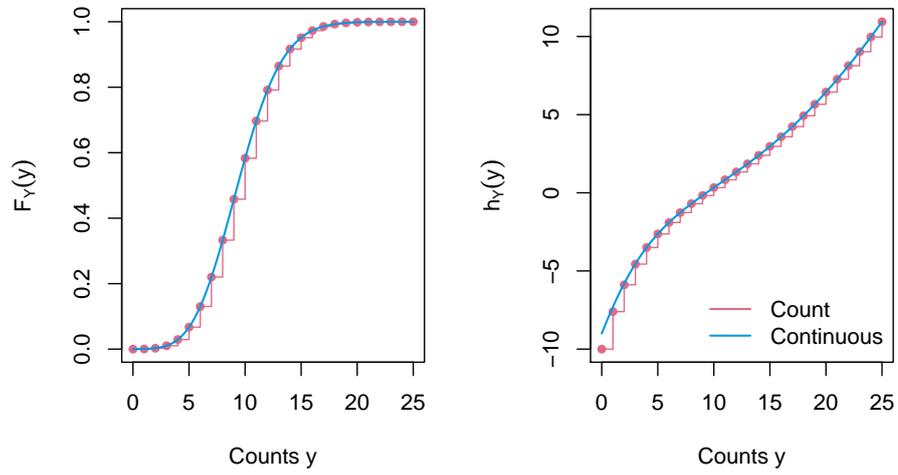

Figure 1: Transformation model. Illustration of a cumulative distribution function ( $F_Y(y) = F_Z(h_Y(\lfloor y \rfloor))$ ), left) and of a transformation function ( $h_Y$ , right) of a count response (red) and a corresponding continuous variable (blue). Note that the two functions coincide for counts  $0, 1, 2, \dots$

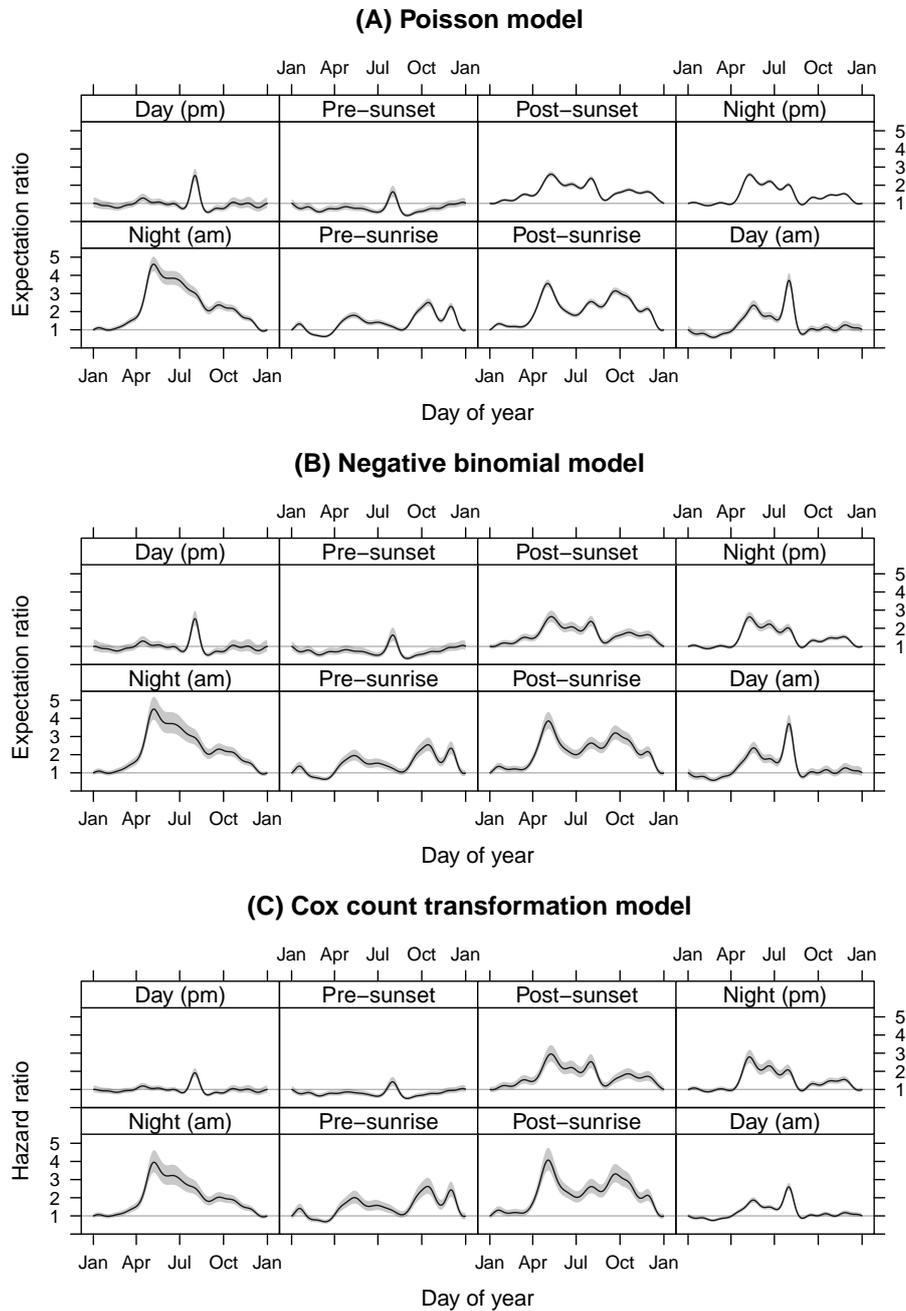

Figure 2: Deer-vehicle collisions. Multiplicative seasonal changes (reference: January 1 at the corresponding time of day) with simultaneous 95% confidence bands for the expected number of deer-vehicle collisions (modelled by the Poisson model with a log link (A) and the negative binomial model with a log link (B)), and for the discrete hazard ratios modelled by the Cox count transformation model (2) (C).

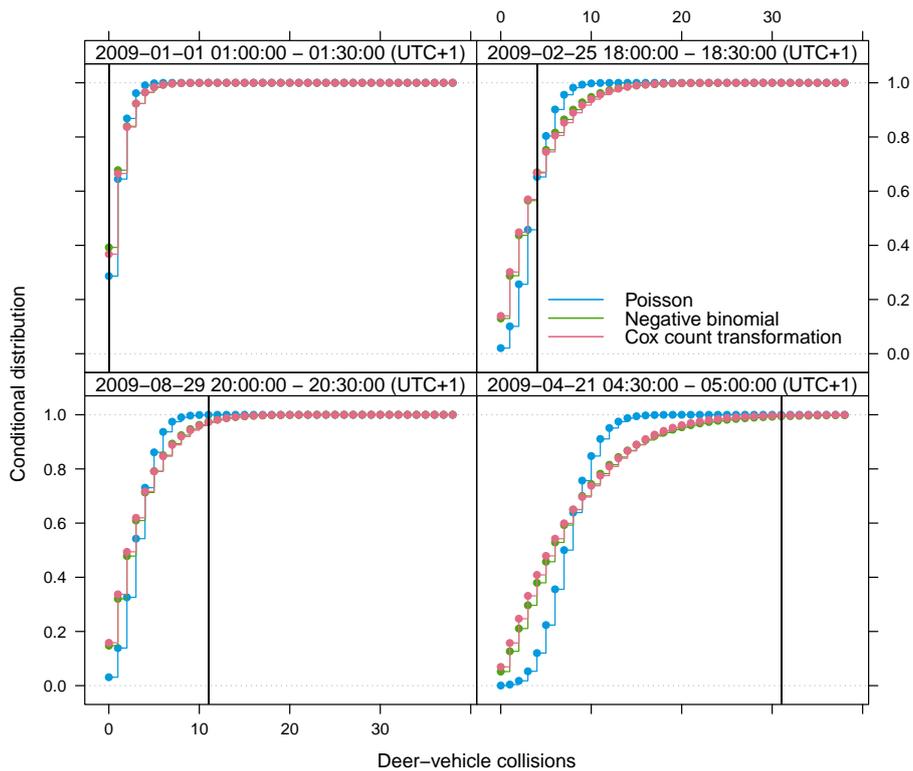

Figure 3: Deer-vehicle collisions. Distributions of the deer-vehicle collision counts conditional on the explanatory environmental parameters of four different time intervals of the year 2009 evaluated for the discrete Cox count transformation model (2) (red), the Poisson model (blue) and the negative binomial model (green). The actually observed deer-vehicle collision counts are shown as a vertical black line.

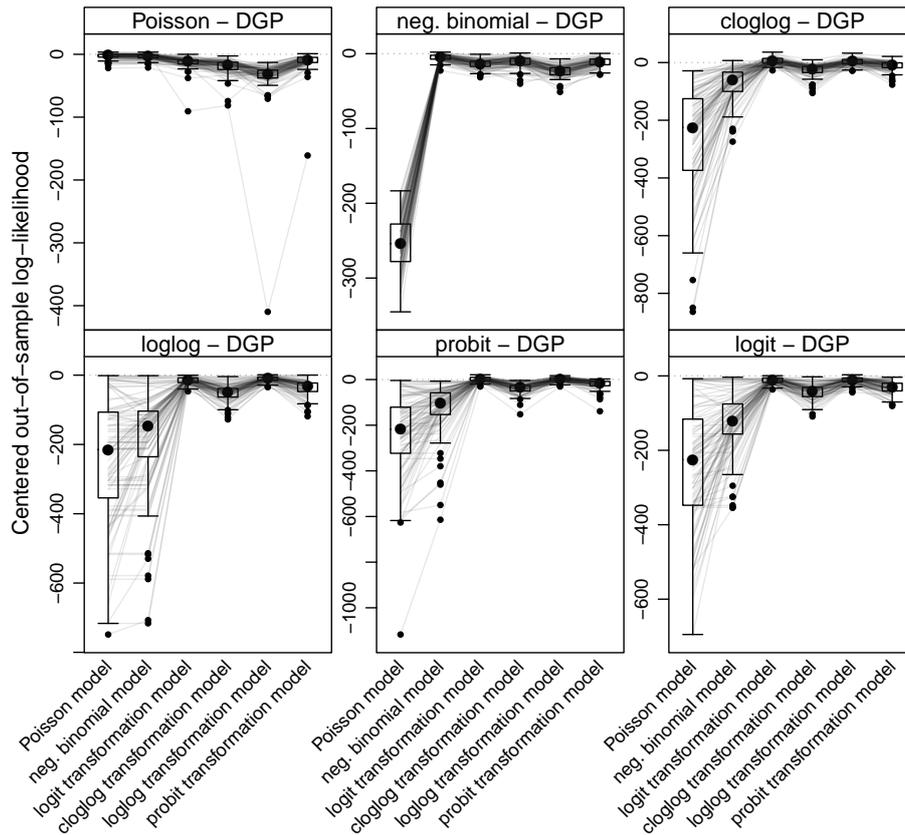

Figure 4: Artificial count-data-generating processes (DGPs). The performance of the count regression models (Poisson, negative binomial and count transformation models outlined in Table 1) assessed by the centered out-of-sample log-likelihood of the corresponding model. Larger values of the out-of-sample log-likelihood indicate a better performance of the corresponding count regression model.

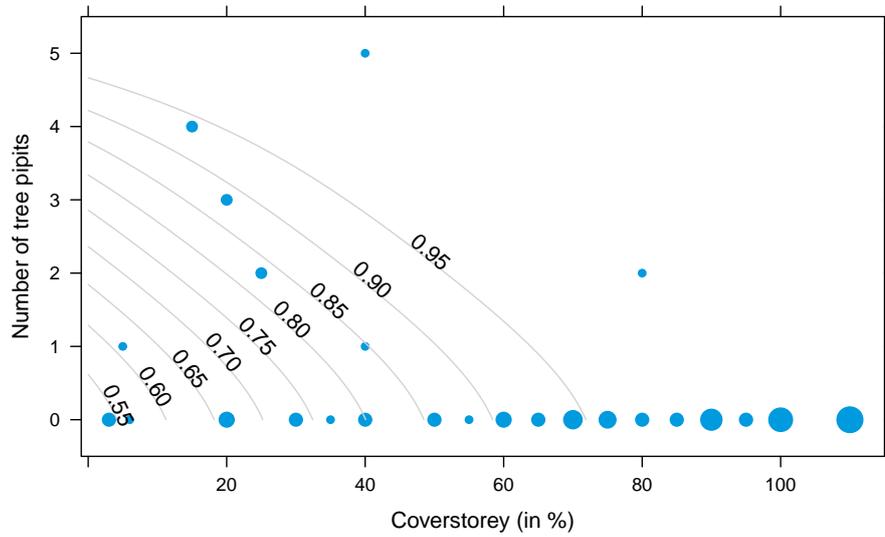

Figure 5: Tree pipit illustration. Number of tree pipits counted at 86 different plots with varying coverstorey. The sizes of the circles are proportional to the square-root of the sample size. Observations are overlaid with the smoothed conditional distribution functions. For a coverstorey of 20%, for example, the probability of not observing any tree pipit is slightly larger than 0.65, the probability of observing at most one tree pipit is somewhat larger than 0.70. For a coverstorey of 60%, the probability of observing at least one tree pipit is less than 0.1.
